

# Evolution of Cytochrome P-450 Proteins<sup>1</sup>

David R. Nelson and Henry W. Strobel

Department of Biochemistry and Molecular Biology, The University of Texas Medical School at Houston

Thirty-four cytochrome P-450 sequences from one bacterial and six vertebrate species have been aligned with the aid of a computer alignment algorithm. Phylogenetic trees were constructed using the unweighted-pair-group and neighbor-joining methods. The two trees differed at only a single branch point near the base of the tree. The cytochrome P-450 superfamily of proteins clustered into eight families and contained 16 gene-duplication events. The first gene duplication occurred ~1,360 Myr before the present (Mybp) and gave rise to cytochrome P-450s found in two different cellular organelles, the mitochondria and the endoplasmic reticulum. Both groups utilize cholesterol or its metabolites as substrates, implying that cholesterol existed >1,360 Mybp. The fourth gene duplication (~900 Mybp) gave rise to the drug-metabolizing P-450s. These proteins aid in the detoxification of foreign chemicals, as opposed to the metabolism of endogenous compounds. The importance of the capacity to metabolize drugs is reflected in 11 further gene duplications occurring in this lineage. The first occurred ~800 Mybp and gave rise to the two major P-450 families, the phenobarbital and 3-methylcholathrene families. An apparent increase in the rate of cytochrome P-450 evolution is noted between the bird-mammal divergence (300 Mybp) and the mammalian radiation (75 Mybp).

## Introduction

Cytochrome P-450 proteins are heme-containing enzymes with an unusual thiolate ( $S^-$ ) ligand to the heme iron. These proteins utilize electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) (or sometimes from reduced nicotinamide adenine dinucleotide) [NADH] to activate molecular oxygen. The reducing equivalents are relayed to the cytochrome P-450 via one or two additional proteins that form a short electron-transport chain. Cytochrome P-450s are found in diverse organisms, from bacteria to plants and animals, implying the existence of a common ancestor before the eukaryote-prokaryote divergence.

The ability to activate molecular oxygen and subsequently to insert one oxygen atom into a substrate has been exploited by organisms for many purposes. Consequently, there are dozens of different cytochrome P-450 molecules even in a single organism. Each P-450 enzyme has a different substrate specificity, but, unlike the situation with most enzymes, the substrate specificity of a single cytochrome P-450 may be quite broad. The substrates are lipophilic molecules frequently containing

1. Key words: cytochrome P-450, evolution, phylogenetic tree, sequence alignment, evolutionary rate increase. Abbreviations: MC = 3-methylcholanthrene; PB = phenobarbital; PCN = pregnenolone-16- $\alpha$ -carbonitrile; UPGMA = unweighted-pair-group method of analysis; PAMs = accepted point mutations; NADPH = nicotinamide adenine dinucleotide phosphate, reduced.

multiple ring structures. Some major functions of cytochrome P-450 proteins include the metabolism of drugs and other foreign compounds, steroidogenesis and bile acid production from cholesterol, and  $\omega$ -oxidation of fatty acids and prostaglandins (for reviews on cytochrome P-450, see White and Coon [1980], Adesnik and Atchison [1985], Nebert and Gonzalez [1985], and Black and Coon [1986]).

Because cytochrome P-450 proteins are so diverse, it will be helpful to categorize them. The first major dichotomy is between eukaryotic and prokaryotic P-450s. The bacterial P-450s form a large class of soluble proteins, in contrast to the eukaryotic enzymes, which are all integral membrane proteins. According to Sligar and Murray (1986), the bacterial cytochrome P-450s "are just as diverse, if not more so, than their eukaryotic counterparts." At present, only one bacterial sequence is known.

Among the eukaryotic P-450s, one bird and 32 mammalian sequences are known. These are found in two cellular locations, the mitochondria (two sequences) and the endoplasmic reticulum (31 sequences). The mitochondrial enzymes catalyze the earliest steps in the conversion of cholesterol into steroid hormones. These proteins have a leader sequence that is removed upon import into the mitochondrion. The endoplasmic-reticulum enzymes are referred to as microsomal P-450s, and they do not have a processed leader sequence, although their N-terminal is very hydrophobic.

The microsomal P-450s can be divided into two groups on the basis of their substrates. The majority of sequenced microsomal P-450s act on compounds foreign to the host cell, such as drugs. They constitute part of a detoxification system and will be referred to as the drug-metabolizing P-450s. The remainder of the microsomal P-450s act on endogenous substrates. They are involved in steroid-hormone biosynthesis and metabolism and in the metabolism of fatty acids and prostaglandins and will be referred to as endogenous P-450s.

Two-thirds of the known P-450 sequences are drug-metabolizing cytochrome P-450s. These proteins can be induced up to 70-fold by the administration of drugs. The proteins fall into two families that are induced by two different classes of drugs, the phenobarbital (PB) family and the 3-methylcholanthrene (MC) family. Table 1 lists the cytochrome P-450 sequences grouped into protein families (nomenclature of Dayhoff [1979, p. 375]). All of these sequences have been described since 1982. There are also several known pseudogene sequences, but they will not be discussed here.

Cytochrome P-450 genes are arranged in multigene families that together constitute a gene superfamily. The actual number of P-450 genes in mammals is not known, but a lower limit may be estimated on the basis of molecular-hybridization studies. Two non-cross-reacting probes have indicated a minimum of 15 genes in the PB family (Atchison and Adesnik 1983; Mizukami et al. 1983a). Five rat and six rabbit P-450 sequences are known, so approximately one-third of the genes in these species have been sequenced. It is not known how many of these genes are functional. The MC family has two or three genes. Two sequences each are known in rats, mice, and humans. Three are present in rabbits. Therefore, the majority of MC-family genes in these species may already be sequenced. The glucocorticoid-inducible P-450<sub>PCN</sub> (also called P-450<sub>p</sub>) shows six to eight hybridization bands (Gonzalez et al. 1985). P-450 C21 is present as two genes in each of cattle, mice, and humans, with only one gene each functional in mice and man (Chung et al. 1986a). The LA <sub>$\omega$</sub>  family contains two or three genes (Hardwick et al. 1987). There are at least six additional P-450 proteins in mammals: P-450 17 $\alpha$ , P-450<sub>scs</sub>, P-450 11 $\beta$ , P-450 aromatase, 25-hydroxy vitamin D<sub>3</sub> 1 $\alpha$ -hydroxylase, and cholesterol 26 hydroxylase. Therefore, the minimum number of P-450 genes is 33, with the possibility that there are others. The chromosomal

<sup>b</sup> Sequence used in this alignment when multiple sequences were available (see text for exceptions).

location of these genes is summarized in table 2 (for a more complete discussion of the genetics of cytochrome P-450, see Adesnik and Atchison 1985).

The present study presents an alignment of 34 sequences and a phylogenetic tree based on both the unweighted-pair-group method of analysis (UPGMA; Sneath and Sokal 1973, pp. 230–234) and the neighbor-joining method of Saitou and Nei (1987). The cytochrome P-450 superfamily of proteins has undergone many gene-duplication events, especially in the PB family of P-450s. Some of the gene duplications appear to have occurred much earlier than previously suspected.

### Material and Methods

Table 1 lists the cytochrome P-450 sequences used in the present study. Sixteen identical or very similar sequences were determined by more than one laboratory or from more than one of the following sources: protein, mRNA, or genomic DNA. Discrepancies were found at 90 of the 7,947 amino acids in these proteins. These differences are listed in the Appendix. Twelve differences are due to incorrect translation of codons into amino acids (P450b alignment positions 82, 187, 230, 270, 295, and 322 [Suwa et al. 1985]; P-450e positions 210, 365, and 460 [Fujii-Kuriyama et al.

<sup>a</sup> Required for the induction of the MC family of P-450s. Two loci appear to be involved.

<sup>b</sup> The electron-transfer protein common to all microsomal P-450s.

1982]; P-450c positions 318 and 337 Hines et al. [1985]; and P1h 444 [Jaiswal et al. 1985*b*]). Four differences (LM2 116, scc bovine 58, cam 403, and cam 580) were probably caused by deamidation of GLN or ASN during peptide isolation. Two highly conserved amino acids (LM2 120 and LM2 121) and four moderately conserved amino acids (LM2 175; LM2 176, LM4 338, and LM4 339) appear to have been inverted. Four amino acids (LM2 124, LM2 125, cam 91, and cam 92) were not detected during amino acid sequencing, but they were present in another sequence. In the paper of Sogawa et al. (1985) a printing error made GLY look like GLU (position 105). Position 526 in P-450<sub>cam</sub> has been confirmed as HIS by means of X-ray crystallography (Poulos et al. 1985). The remaining 62 differences were not as easily explained. They may have been caused by sequencing distinct genes or polymorphic alleles of the same gene, or they could be due to sequencing error. Thirteen differences occurred at positions of 100% conservation within the alignment of the PB or MC families (PB1 326, b 474, LM4 28, LM4 59, LM4 194, LM4 270, LM4 281, d 44, d 158, d 305, d 469, P3 449, and P1h 444). The last was a codon-translation error mentioned above. Three additional differences (LM4 509, 23/25 sequences; LM4 581, 8/9 sequences; and C21h 520, 32/33 vertebrate sequences) showed very high conservation of a particular amino acid. These 16 differences may represent sequencing errors, although a genetic difference at these positions is possible. In these cases, the conserved amino acid was used in the alignment. The remaining 46 differences belong to two different types of sequences, those in families known to have multiple genes and those in families with one or a very low number of functional genes; P-450s f, PB1, 3b, e, LM2, and HLP fall into the first group, and P-450s c, P1h, LM4, and C21 bovine are members of the second group. Differences (not already discussed) between sequences in the first group probably represent differences between distinct genes, although some differences may be due to polymorphic alleles or sequencing errors; differences (not already discussed) between sequences in the second group are unlikely to represent differences between distinct genes but are more likely due either to differences between polymorphic alleles or to sequencing errors. The sequences chosen for use in this alignment

when more than one sequence were available are indicated by a superscript b in table 1, with the following exceptions: The complete P-450 3b amino acid sequence of Ozols et al. (1985) was used except at positions 115, 281, 418, and 517, where the incomplete cDNA sequence of Leighton et al. (1984) more closely resembled sequences 1–5. The complete LM4 sequence of Ozols (1986) was used except at positions 28, 194, 338, and 339, where the sequence of Fujita et al. (1984) was favored for reasons already mentioned. The P-450d sequence of Kawajiri et al. (1984) was used except at position 305, where PHE is favored over SER, as per Haniu et al. (1986) and Sogawa et al. (1985). The human p-like sequence (HLP or nifedipine oxidase) of Beaune et al. (1986) was used except at position 343, where LYS was favored over a gap in the sequence. The chosen sequences more closely resembled other sequences in their respective families.

#### Alignment of Amino Acid Sequences

Alignment of P-450 sequences within families was done manually because these sequences were >40% identical in the PB family and >60% identical in the MC family. Sequence alignment between these two families was achieved by comparing cytochrome P-450c with cytochrome P-450e by means of the alignment algorithm of Needleman and Wunsch (1970) as modified by Gotoh (1982). The gap-weighting factor in this program was  $2k + 3$ , where  $k$  is the gap width. The computer-generated alignment of P-450c and P-450e was used to align the two large sets of sequences. Some judgment was used in this process. The more distantly related sequences—P-450s 17a, C21b, p, scc, and cam—were aligned with cytochrome P-450e by computer. The gap-weighting factor was increased in some instances to  $4k + 3$  or to  $5k + 3$  to make gaps less likely. Once the computer-generated alignments were available, the sequences were individually incorporated into the larger body of sequences by using the computer alignment as a guide. Because of the large number (561) of pairwise comparisons involved, computer alignment of all the pairs was neither practical nor deemed necessary. After the initial alignment was completed, the overall length of the alignment was shortened by 10%, from 660 positions to 594. The longest sequence was 524 amino acids. In this shortening procedure, the number of gaps was reduced by 50%. The alignment of all 34 sequences is shown in figure 1.

#### The Phylogenetic Tree of Cytochrome P-450 Proteins

The 34 cytochrome P-450 sequences were analyzed for the number of identities in 561 pairwise comparisons. Only those portions of the molecules that overlapped were compared. Twenty nine of the 34 sequences are complete. Two others (PBc1 and PBc2) are >97% complete. P-450 6 and P-450 4 are ~90% and ~82% complete, respectively. The human P-450 sequence of Phillips et al. (1985a) is two-thirds complete. The alignment contains a total of 16,659 amino acids. Gaps were not counted as differences and did not contribute to the overall length of the sequences compared. Once a percentage difference had been obtained for each pair, the evolutionary distance in accepted point mutations (PAMs) was estimated by using table 36 of Dayhoff (1979, p. 375). To simplify conversion of percentage difference values to PAM values, the following three equations, which closely approximate the PAM values over given ranges of percentage difference, were used:

$$-0.808 \ln(2 - 2.5x) + 0.56$$

$$0.01 \leq x \leq 0.60; \quad (1)$$

FIG. 1 (Continued)

These equations yield PAMs/100, where  $x$  is the percentage difference/100. Table 3 contains the percentage differences between all the pairs of cytochrome P-450 sequences (above the diagonal) and the number of identities between pairs (below the diagonal). A UPGMA phylogenetic tree was constructed by using the evolutionary-distance ( $d$ ) values obtained by applying equations (1-3) to the percentage difference data of table 3. A second phylogenetic tree was constructed by using the neighbor-joining method of Saitou and Nei (1987). This method is a minimum-evolution method; that is, it does not assume a constant rate of evolutionary change in all branches of the tree. The program was obtained in FORTRAN and converted to BASIC

FIG. 1 (Continued)

for use on an IBM XT with a BASIC compiler. To produce a rooted tree for comparison with the UPGMA tree, a set of dummy data was included as an outgroup.

## Results

### The Phylogenetic Tree

Figure 2 depicts the UPGMA phylogenetic tree of cytochrome P-450 proteins. The branching pattern is the same as that obtained before reducing the number of gaps by half, and it is the same whether gaps are not counted in the computation of percentage difference or are counted as single replacements. If a gap of length  $n$  is

FIG. 1 (Continued)

counted as  $n$  replacements, an extreme case, the pattern has only one change. The lauric acid  $\omega$ -hydroxylase ( $LA_{\omega}$ ) sequence clusters with the two side-chain cleavage sequences ( $P-450_{\text{sc}}$ ) rather than forming a separate branch.

The phylogenetic tree produced by the neighbor-joining method, with an outgroup included, is remarkably similar to the UPGMA tree. When gaps are not included in the calculation of percentage difference, the neighbor-joining method produces a tree with only one difference in the branching pattern. Again, the  $LA_{\omega}$  sequence clusters with the two  $P-450_{\text{sc}}$  sequences. This pattern also remains the same if gaps of length  $n$  are counted as single replacements or as  $n$  replacements. These two independent

NOTE.—Sequence numbers are as in fig. 1.

methods give essentially the same tree, with only one minor difference in tree topology. The integrity of this branching pattern under these extremely varied assumptions argues for its correctness.

#### A Time Scale for the Phylogenetic Tree

Since most of the sequences in figure 1 are mammalian, calibration of  $d$  with time will be most accurate for times more recent than the mammalian radiation. To fix the time scale for the more ancient part of the tree, the divergence between bacterial and eukaryotic P-450s ( $d = 2.5$ ) has been set at 1,400 Mybp, the date of the earliest eukaryotic microfossils (Vidal 1984). If this and zero were the only points used in the calibration, the divergences between rabbits, humans, and rodents would fall at  $\sim 150$  Mybp ( $d$  for eight divergences  $0.27 \pm 0.04$ ). Clearly this is unsatisfactory, since the mammalian radiation is commonly considered as having occurred  $\sim 75$  Mybp (McLaughlin and Dayhoff 1972). To avoid this problem we have chosen the bird-mammal divergence time of 300 Mybp (Dickerson 1971; Romero-Herrera et al. 1978)

to calibrate the  $d$  scale from the chicken-mammal divergence ( $d = 0.71$ ) to the prokaryote-eukaryote divergence ( $d = 2.51$ ). To calibrate the low end of the scale, the rat-mouse divergence ( $d = 0.072$ ) was assumed to have occurred  $\sim 20$  Mybp (Miyata et al. 1982; Shoshani et al. 1985). By this choice, the mammalian radiation (estimated at  $d = 0.27$ ) occurred  $\sim 75$  Mybp. The break in the time scale may reflect an increase in evolutionary rate that occurred since the bird-mammal divergence. The estimates of time in the oldest part of the tree are subject to the largest error. It is to be hoped that sequences of P-450s from more nonmammalian sources will soon be available to improve the estimation of a time scale in this part of the tree.

#### Features of the Tree

There are two major divisions among sequences in this phylogenetic tree. The first involves the separation between eukaryotic and prokaryotic sequences. This branch point represents the base of the tree. The second division is between endogenous P-450s (sequences 24–33) and drug-metabolizing P-450s (sequences 1–23). The gene duplication giving rise to the drug-metabolizing P-450s occurred  $\sim 900$  Mybp. This

FIG. 2.—UPGMA phylogenetic tree of 34 cytochrome P-450 proteins. Black diamonds indicate gene-duplication events because the same species occurs on both sides of the branch point. An asterisk marks a presumed gene duplication, because the time of the event is too early to represent a species divergence (i.e., rats did not diverge from rabbits 120 Mybp). Unmarked branch points represent species divergences.

group subsequently separated into two distinct families ~800 Mybp. No further branchings occur until ~400 Mybp, when the PB family began to undergo a phenomenal ramification. This period in time corresponds to the Devonian period of the Paleozoic era, the period when vertebrate ancestors began to colonize the land.

### Rates of Cytochrome P-450 Evolution

The rate of cytochrome P-450 evolution was calculated from the  $d$  values for species-divergence events in figure 2 and from geologic dates for the various divergence events. The rates in amino acid changes per site per year and the unit evolutionary period are listed in table 4. The rates are well below the maximum rate of  $\sim 9 \times 10^{-9}$  reported for fibrinopeptides (McLaughlin and Dayhoff 1972). There is, however, an approximately twofold difference between the maximum and minimum rates. All the rates for mammals diverging from mammals are greater than the rates both for mammals diverging from birds and for prokaryotes diverging from eukaryotes.

### Discussion

The early history of cytochrome P-450 proteins appears to be related to the evolution of cholesterol and its metabolites. The earliest eukaryotic P-450 sequences yet known are the mitochondrial P-450<sub>sc</sub> sequences. These enzymes catalyze cholesterol side-chain cleavage to produce pregnenolone, the precursor of all steroid hormones. The evolution of P-450<sub>sc</sub> must have preceded the divergence of plants and animals,

<sup>b</sup> Calculated from the equation  $d = 2\lambda$ , where  $\lambda$  is the rate of change (Tajima and Nei 1984).

<sup>c</sup> Time required for a 1% difference in sequence to occur, calculated by dividing the divergence time by the evolutionary distance  $\times 100$ .

because it is found in plants that make cardiac glycosides. Therefore, plants diverged from animals before the first gene duplication shown in figure 2 ( $\sim 1,360$  Mybp). An even older connection exists between P-450 and cholesterol, because a P-450 enzyme is required to synthesize cholesterol, e.g., to remove the 14 methyl group from lanosterol. Apparently, P-450 proteins were adapted for use in the biosynthesis of cholesterol even before the divergence of prokaryotes from eukaryotes, because there are three types of bacteria known to contain—and presumably synthesize—cholesterol or partially demethylated lanosterol derivatives (Bloch 1983).

The only eukaryotic sequence of the 10 endogenous P-450s in figure 2 that does not act on cholesterol or its derivatives is P-450 LA<sub>ω</sub>. This sequence shows some ambiguity in its branching on the tree, sometimes clustering with the P-450<sub>sc</sub> sequences. Some bacterial P-450s are ω-hydroxylases of alkanes (Sligar and Murray 1986). Furthermore, P-450 cholesterol 26 hydroxylase, a mitochondrial enzyme, also hydroxylates the end of a long lipid. These two proteins, one mitochondrial and one microsomal, may be related in their function. It is not possible to tell whether the LA<sub>ω</sub> sequence is a bacterial relic or a more recent branch from the cholesterol-related P-450s.

As mentioned earlier, eukaryotic P-450s are found in two cellular locations, the mitochondria and the endoplasmic reticulum. These two types of P-450 proteins receive electrons from two very different sources. The mitochondrial P-450s are reduced by an iron-sulfur protein called adrenodoxin, which is first reduced by adrenodoxin reductase, a flavoprotein. The microsomal P-450s are reduced by a single protein called NADPH cytochrome P-450 reductase, which contains two different flavins. The prokaryotic P-450<sub>cam</sub>, like the mitochondrial P-450s, receives electrons from an iron-sulfur protein that is first reduced by a flavoprotein. The similarity between the bacterial and mitochondrial systems suggests that the mitochondrial P-450s derived from a bacterial ancestor. At the same time, the difference between adrenodoxin and NADPH cytochrome P-450 reductase implies a different origin for the microsomal P-450s. One possible explanation is that the two different types of P-450s came from the two unique lineages that united to form the first eukaryote. More sequences of bacterial and mitochondrial P-450s and their reductase proteins will be needed to decide whether this speculation is correct.

Perhaps the most significant event in P-450 evolution was the gene duplication  $\sim 900$  Mybp. One of the resultant lineages continued to function as an endogenous type of P-450. The two different genes in this branch code for enzymes in the biosynthetic pathway of cortisol. The other branch began a new function for cytochrome P-450, the detoxification of lipid-soluble foreign compounds. This later lineage then soon ( $\sim 800$  Mybp) divided into the two major P-450 families, the PB and MC families. Approximately 400 Mybp the PB family began diversifying. Since then, there have been eight gene duplications in this branch of the tree. The impetus for this striking diversification may have been the abrupt exposure of vertebrates to toxic chemicals in land plants. Plants preceded vertebrates on land by several million years, giving the plants ample time to develop chemicals never before experienced by the previously water-bound vertebrates. The evolution of detoxification enzymes such as the drug-metabolizing P-450 proteins would have been highly advantageous.

The date estimated here for the divergence of the PB and MC families is twice as far in the past as the date estimated by Sogowa et al. (1985). Similarly, estimates of the time of divergence between the PCN family (P-450s HLP and p) and the lineage leading to the drug-metabolizing P-450s are much lower than depicted in figure 2. Gonzalez et al. (1985) estimate that the PCN family divergence occurred at much

more than 200 Mybp. Hobbs et al. (1986) estimate that it occurred 600 Mybp. In figure 2, this divergence occurs  $\sim 1,100$  Mybp. The reason for these differences lies in the fact that figure 2 has a break in the time scale. This break exists because it was not possible, when using a single scale, to reconcile the  $d$  values with estimated dates for either the divergence of reptiles and mammals (equivalent to the chicken-mammal divergence) or divergences between mammals. For example, if 17 Mybp is assumed for the rat-mouse divergence (as in Gonzalez et al. 1985), then the PB/MC split falls at  $\sim 370$  Mybp but the chicken-mammal divergence falls at  $\sim 175$  Mybp. Similarly, use of a rodent-human divergence time of 60–80 Mybp (as in Kawajiri et al. 1984; Gonzalez et al. 1985) will result in the PB/MC split occurring at  $\sim 340$ – $450$  Mybp but the bird-mammal divergence at  $\sim 160$ – $210$  Mybp. Both Dickerson (1971) and Romero-Herrera et al. (1978) give the bird-mammal divergence as  $\sim 300$  Mybp. There are two ways to resolve this problem. Either the  $d$  value for the bird-mammal divergence is underestimated by  $\sim 80\%$  or there must be a break in the time scale. An error of this magnitude is hardly believable for a  $d$  value of 0.7. The variation in 12 mammal-mammal divergences in table 4 is only 15%. This variation reflects the random nature of evolutionary change. Certainly, the error at the chicken-mammal divergence is not much greater than this. Consequently, the assumption that there is a break in the time scale of figure 2 seems justified.

The most likely reason for a break in the time scale is an acceleration in the evolutionary rate after the bird-mammal divergence. Table 4 indicates the rate of evolutionary change for 14 mammal-versus-mammal divergence events as being  $1.83 \pm 0.23 \times 10^{-9}$  changes  $\cdot$  site $^{-1} \cdot$  year $^{-1}$ . The bird-mammal and the prokaryote-eukaryote divergences yield rates of  $1.18 \times 10^{-9}$  and  $0.90 \times 10^{-9}$  changes  $\cdot$  site $^{-1} \cdot$  year $^{-1}$ , respectively. Between the bird-mammal divergence and the mammalian radiation, there appears to have been an increase of 55%–100% in the cytochrome P-450 evolutionary rate. Even if the rates for the earlier divergences are in error, the magnitude of the error seems unlikely to be 55%–100%. The observation of an increase in the rate of evolution is not unique to cytochrome P-450. Such an increase in evolutionary rate in the mammalian lineage has been proposed during the same time period for cytochrome  $c$ ,  $\alpha$  and  $\beta$  hemoglobins, and myoglobin (Baba et al. 1981; Goodman 1981; Shoshani et al. 1985). The increase in rate has been linked to the rapid divergence of species during major adaptive radiations. Recently, Catzeflis et al. (1987) have given evidence that the evolutionary rate in rodents is 10 times the rate in hominoids and birds. The reason for the change in rate is unknown, but these authors propose that differences in DNA repair mechanisms may be involved. Britten (1986) finds a similar difference in rate (i.e., approximately fivefold) between rodents, hominoids, and birds. If the rate of evolution can vary 5–10-fold, then the need for multiple time calibrations is clearly indicated. Furthermore, Kunisawa et al. (1987) have found that a molecular clock based on vertebrate amino acid sequences of cytochrome  $c$  greatly underestimates divergence times among bacteria. These authors suggest that a multiclock model, one that posits a slower rate of evolution for earlier times periods, is needed to make reliable phylogenetic trees from amino acid data. A break in the time scale, identical to that seen in figure 2, is seen in figure 3 of Shoshani (1986).

On the basis of these considerations, the time scale in figure 2 seems justified. The earlier dates for divergence of the PB and MC families and other gene duplications are probably more accurate than dates derived by extrapolation from divergences among mammals. Certainly there is need for further revision of the time scale as more sequences of earlier-existing vertebrate and nonvertebrate P-450s become available.

## Acknowledgments

Many thanks are due to Dr. J. C. Stephens for numerous discussions, a critical reading of the manuscript, and a copy of his UPGMA-tree computer program. E. Naruya Saitou wrote the FORTRAN version of the modified Needleman-Wunsch algorithm according to Gotoh (1982) and the neighbor-joining program. This study was supported by grant AU1067 from the Robert A. Welch Foundation and by grant CA37148 from the National Cancer Institute, Department of Health and Human Services.
